Progress of head and neck surgery in China over the last 20 years

BY YUEYING MA AND LIANGFA LIU

Although China was late to establish head and neck surgery in comparison to other areas of oncological surgery, with the persistent hard work of head and neck surgeons nationally, it has progressed significantly during the last two decades. Yueying Ma and Liangfa Liu discuss this development.

Head and neck as a separate surgical specialty was established in China in the early 1950s. The professional commission of head and neck surgery was formally constituted in 1985. Most head and neck surgeons in our country work almost exclusively in dedicated departments of head and neck surgery at cancer hospitals or oral and maxillofacial surgery of general hospitals, or oral and maxillofacial surgery in hospitals of stomatology (or dental hospitals). Each of these departments is complementary and has its respective contributions. In China, we have tried to keep up with the cutting edge techniques practised in the leading centres of the world, including multidisciplinary treatment of head and neck cancer, skull-base tumour surgery, laryngeal preservation in laryngeal carcinoma and hypopharyngeal carcinoma, functional reconstruction of head and neck after radical tumour resection, and minimally invasive head and neck surgery [1]. During the past 20 years, with the introduction of new technology and techniques, head and neck surgery in China has developed rapidly throughout the country.

Based on the death survey data of 2008 from the Cancer Hospital of Chinese Academy of Medical Sciences (age-standardised incidence rates) head and neck cancer was in the top 20 cancers estimated in China in 2008 including: esophageal cancer (fourth in male and seventh in female); nasopharyngeal cancer (11th in male); laryngeal cancer (14th in male); and thyroid cancer (13th in female) [2]. Based on the data of the latest cancer statistics in 2015 from the same hospital, 477,900 new esophageal cancers and 90,000 new thyroid cancers were estimated in 2015 [3]. This shows that currently laryngeal, thyroid and esophageal malignancies are still the main focus of head and neck surgery.

Radical surgery for head and neck cancer has often resulted in organ dysfunction, morbidity and disfigurement but with increasing economic prosperity, patients now aspire to better quality of life. The head and neck surgeons have to pay more attention to preservation of function and reconstruction of organs, along with radical resection. Surgery with laryngeal preservation and functional reconstruction is being practised for advanced laryngeal and hypopharyngeal carcinomas. Orbital preservation and function has to be taken into account in paranasal sinus cancer operations. Reconstruction of the maxilla and mandible with flaps and dental implants are widespread in maxillofacial oncological surgery.

Multi-centre studies have shown that open laryngeal surgery, laser microlaryngeal surgery and primary radiotherapy have similar survival rates for early glottic cancer in our country. Like in the west, transoral laser microsurgery for early laryngeal cancer has been adopted widely at different head and neck centres in China [4]. For T2 glottic laryngeal cancer, vertical partial laryngectomy could get about a 90% five-year postoperative survival rate and an 80-100% decannulation rate [5]. Supracricoid partial laryngectomy (with cricohyoidoepiglottopexy) could get an 88-90% five-year postoperative survival rate and a 98-100% decannulation rate [6]. Some laryngeal preservation surgery for advanced laryngeal cancers has also achieved good outcomes.

“Like in the west, transoral laser microsurgery for early laryngeal cancer has been adopted widely at different head and neck centres in China.”

Radial forearm free flaps and free anterolateral thigh flaps have been used to repair supraglottic structures for laryngeal preservation after partial laryngectomy in patients with advanced hypopharyngeal...

disease of the nasal cavity, paranasal sinuses and skull-
base for nearly three decades in Europe and North America. In recent years, surgeons
in our country have tried to use endoscopic sinus surgery in most paranasal benign
tumours, including sinonasal inverted papillomas, nasopharyngeal angiofibroma,
and even some localised intranasal and sinus carcinomas. Endoscopic skull base surgical resection and reconstruction has also developed over the last decade with excellent outcomes. In some large tertiary head and neck centres, image-guided systems are used in conjunction with endoscopic sinus surgery to recognise and preserve important structures, reduce complications, ensure good tumour excision margins, and improve total resection rate along with reduced postoperative morbidity.

Three-dimensional rapid prototyping is a new technique which has been used and developed in many medical fields and is especially popular in maxillofacial head and neck surgery, including operation planning, simulated operation and making individualised implant prosthesis. In China, Sun first attempted to reconstruct the maxilla and mandible with supplementary three-dimensional rapid prototyping, and has reported more than one hundred such procedures so far. Reducing disabling morbidity associated with cranial nerve paresis during head and neck tumour resection is a key objective of most head and neck surgeons. In recent years, intraoperative cranial nerve monitoring is widely being applied in head and neck surgery in an attempt to improve surgical outcomes. Wang reported his successful preservation of the facial nerve function during parotid gland surgery with intraoperative facial nerve monitoring. Recurrent laryngeal nerve and vagus nerve monitoring is also being increasingly applied in thyroid gland surgery in many institutions, and helps with training and improved outcomes. In endoscopic optic nerve decompression, sinus endoscopic optic surgery involving orbit and anterior skull base, intraoperative optic nerve monitoring is helping to avoid optic nerve injury.

A new generation of lymphatic tracers, nanocrystalline carbon has been widely used in surgery of gastric cancer and breast cancers, guiding lymph node resection and sentinel lymph node biopsy. In recent years, nanocrystalline carbon tracers have been applied in thyroid gland surgery. Zhang found that there are different lymphatic drainage pathways between thyroid glands and parathyroid glands, and nanocrystalline carbon tracing could help improved localisation of parathyroid glands. Zhu and his colleagues reported that they could help preserve parathyroid glands and the vagus nerve, and thus reduce complications and plan lymph node dissection more accurately and completely with nanocrystalline carbon tracer application in thyroid gland surgery. Some surgeons also apply nanocrystalline carbon into sentinel lymph node mapping in head and neck cancer. Ren and his colleague used nanocrystalline carbon mixed suspension to detect sentinel lymph node in 20 cN0 laryngeal cancer operations, and in 19 out of 20 displayed sentinel lymph node successfully (detection rate is 95%). Guan et al injected nanocrystalline carbon mixed suspension in the margin of tumour preoperatively in 45 patients with oral squamous cell carcinomas, and guiding cervical lymph node dissection with lymph node black staining.

The history of radioactive seed implantation in treatment of cancer is more than 100 years in Europe and USA. Our scientists developed iodine seeds (model 6711) and applied them in clinical practice over the last two decades. The application and approach of radioactive seed implantation in head and neck surgery has also been applied selectively. In 2006, Zhang and colleagues treated 36 cases of oral and maxillofacial malignancy with CT-guided iodine seed implantation and followed for 6
to 36 months, with no recurrence found in target region [20]. In 2010, Qiao et al treated 45 cases of oral and maxillofacial malignant tumours (47 lesions) with iodine125 seed implantations under ultrasound-guidance, and the application was generally very accurate [21]. In 2014, Feng and colleagues first implanted the iodine125 seed with the guidance of a three-dimensional printing model for a patient with a maxillary sinus tumour. Compared with CT or ultrasound guidance, the three-dimensional printing model meant less operative time and improved accuracy with better effects [22]. The management of head and neck malignancy needs multidisciplinary cooperation, and improving survival rate and pursuing quality of life at the same time is our ultimate objective. At present in China, most of the head and neck centres have set up multidisciplinary consultation procedures, that utilise multiple current management modalities (including surgery, radiotherapy, chemotherapy, bio-immunotherapy, gene therapy and Chinese traditional treatment) comprehensively in a planned way, in order to improve cure rate and quality of life markedly [23]. In conclusion, with progress of new sciences and techniques, head and neck surgery in China is developing steadily and aspiring to provide a world class service.
